Grazing-incidence x-ray diffraction and atomic force microscopy were performed on bulk heterojunction regioregular poly(3-hexylthiophene) (RR-P3HT) [6,6]-phenyl-C71-butyric acid methyl esters spin-cast films with different film processing conditions to correlate the crystalline nanostructure of P3HT with the corresponding solar cell performance. The increase in long wavelength absorption for solvent annealed films is related to highly conjugated crystal structure of RR-P3HT phase-separated in the active layer. Upon thermal annealing, the solvent annealed 50-nm-thick device shows high solar cell performance with fill factor up to 73% and power conversion efficiency of 3.80%. © 2008 American Institute of Physics. [DOI: 10.1063/1.2891884]

Bulk heterojunction (BHJ) solar cells1 based on regioregular poly(3-hexylthiophene) (RR-P3HT) and fullerene have achieved 4–5% power conversion efficiency (PCE).2–10 The incident photon conversion efficiency (IPCE) is approaching that of that of their inorganic semiconductor counterparts.3,4,6,8 The major limitation is the absorption of polymer solar cells efficiency via multiple device stacking or tandem structure. 25 nm of Ca and 100 nm of Al were thermally evaporated onto the glass substrate to form the top. Figure 1 shows 2D GIXRD patterns of P3HT/PCBM films from solutions in DCB (for 1 and 2) and CB (for 3 and 4). For the sample 2, DCB is completely evaporated during spin casting at 1000 rpm for 90 s, while a relatively short time of 30 s provides solvent-annealing effect on the sample 1 still containing small amounts of the solvent residue. The film thickness is ~150–160 nm. In the 2D GIXRD patterns of the two samples, intense reflections of (h00) and (010) crystal planes of RR-P3HT are indicated along the qxy axis, respectively, corresponding to π-conjugated planes in RR-P3HT crystals, where hexyl side chains of RR-P3HT have an edge-on structure with respect to the substrate. In contrast, fast solvent evaporation conditions by relatively volatile CB induce less-ordered crystalline structure of RR-P3HT in the sample 3 (1000 rpm, 90 s) and 4 (3000 rpm, 90 s), as confirmed in AFM topography showing less crystalline RR-P3HT [Fig. 1(d)]. In addition, samples 3 and 4 contain high portion of kinetically favorable face-on structure of RR-P3HT crystals (i.e., the side chain parallel to the substrate), as confirmed by intense reflection of (010) crystal planes (with a layer spacing of 3.8 Å) along the qxy axis in the 2D GIXRD patterns.14,15 From one-dimensional (1D) out-of-plane X-profiles for the P3HT/PCBM films examined [Fig. 1(b)], we found that sample 1 with the longest crystal growth time has the highest crystallinity, although the edge-on molecular ordering becomes broader by crystal growth of RR-P3HT in a pseudosolidlike state [Fig. 1(c)]. An increase in polymer interlayer spacing is clearly observed—16.3 Å in 1, 16.5 Å in 2, 16.8 Å in 3, and 16.9 Å in 4. As a result, the controlled evaporation rate of high boiling solvent is one strategy to induce highly ordered and crystalline RR-P3HT in the blend film. This provides freedom to make high efficient solar cells with wide various film thickness.

The polymer solar cells in this study were constructed on indium tin oxide (ITO) coated glass substrates modified by PEDOT:PSS. In order to systematically control solvent evaporation rate, RR-P3HT/PCBM (20:20 mg/ml) was dissolved in 1,2,4-trichlorobenzene (TCB) with a high Tg of 144 °C. The active layer was deposited by spin casting at 3000 rpm (~50 nm, measured by Dektek profilometer). The slow growth process is carried out by covering active layer in a petri dish immediately after spin casting for 50 s. By spin casting at 3000 rpm for 180 s, the film was completely dry and hereby still referred as “fast growth.” Thermal annealing is at 110 °C for 15 min. The absorption measurement was performed using Varian Cary 50 UV-visible spectrophotometer. 25 nm of Ca and 100 nm of Al were thermally evaporated on...
rated through a shadow mask under a vacuum of 10⁻⁶ Torr. Testing procedures follow Ref. 4.

Figure 2 shows the effect of growth process on the absorbance for the thin films of RR-P3HT:[70]PCBM (1:1 wt %), before and after thermal annealing at 110 °C. Although the fast-grown film is more homogeneous and smooth, the spectral features of P3HT subsides dramatically, which is attributed to [70]PCBM induced destruction of the RR-P3HT chain packing (ordering). On the other hand, the absorption spectra of solvent annealed film has very pronounced vibronic peaks, indicating strong interchain interaction among RR-P3HT chains as well as phase segregation. Thermal annealing significantly enhances the absorption of fast-grown film in long-wavelength region, although cannot match that in solvent annealed films. This indicates that the latter is more efficient in enhancing RR-P3HT chain packing and crystallinity. The IPCE data follow the same trend among RR-P3HT chains as well as phase segregation. The best device performance is achieved with slow-grown film combined with thermal annealing at 110 °C (J_{SC}=8.59 mA/cm², V_{OC}=0.62 V, FF=71.3%, and PCE=3.80%). Thermally annealed fast-grown device gets major boost in J_{SC} (from 3.21 to 7.56 mA/cm²) and FF (from 29.8% to 53.3%). As expected, the resulting 2.49% PCE is significantly lower than that of purely solvent annealed device.

The V_{OC}, J_{SC}, and FF of the device with both solvent and thermal annealing as function of the incident light intensity (P_{in}) are plotted in Fig. 3(b). FF reaches a maximum of 73.1% at an incident intensity of 20 mW/cm². The FF remains at 71.3% at AM1.5G 100 mW/cm² illumination. These values are among the highest reported numbers in organic solar cells so far. The improved FF provides hint of improved transport property, which could be attributed to the fact that the charge became easier to extract due to the lower thickness of active layer. Table I summarizes the solar cell performance.

leads to a percolated network of both crystalline RR-P3HT and PCBM, i.e., a quasi-optimized morphology for polymer solar cells with two types of active layers: fast grown and slow grown.

The performance improvement through solvent annealing can be explained by film morphology. While RR-P3HT self-organizes to fibrillar highly crystalline domains with per-diothermicity close to twice the exciton diffusion length, it leads to a percolated network of both crystalline RR-P3HT and PCBM, i.e., a quasi-optimized morphology for polymer solar cells. PCBM is believed to play a minor role because solvent annealing is at room temperature.

In conclusion, we have shown that film processing conditions can control polymer nanoscale crystallinity and phase separation using GIXRD and AFM techniques. Efficient polymer solar cells (3.80% under AM 1.5G illumination at 100 mW/cm^2) based on thin P3HT:PCBM heterojunction with low optical density have been demonstrated. The enhancement of the J_{SC} and FF of the solvent annealed device with thermal treatment compared to the fast-growth device without thermal treatment is attributed to increase absorption in red region and improved charge transfer properties.
